Combinatorics of first order structures
and propositional proof systems

Abstract

We define the notion of a combinatorics of a first order structure, and a relation of covering between first order structures and propositional proof systems. Namely, a first order structure $M$ combinatorially satisfies an $L$-sentence $\Phi$ iff $\Phi$ holds in all $L$-structures definable in $M$. The combinatorics $\text{Comb}(M)$ of $M$ is the set of all sentences combinatorially satisfied in $M$. Structure $M$ covers a propositional proof system $P$ iff $M$ combinatorially satisfies all $\Phi$ for which the associated sequence of propositional formulas $\langle \Phi \rangle_n$ encoding that $\Phi$ holds in $L$-structures of size $n$, have polynomial size $P$-proofs. That is, $\text{Comb}(M)$ contains all $\Phi$ feasibly verifiable in $P$. Finding $M$ that covers $P$ but does not combinatorially satisfy $\Phi$ thus gives a super polynomial lower bound for the size of $P$-proofs of $\langle \Phi \rangle_n$.

We show that any proof system admits a class of structures covering it; these structures are expansions of models of bounded arithmetic. We also give, using structures covering proof systems $R^*(\log)$ and $PC$, new lower bounds for these systems that are not apparently amenable to other known methods. We define new type of propositional proof systems based on a combinatorics of (a class of) structures.

We continue here research into what could be called infinite limits of polynomially bounded propositional proof systems. Although this is best explained on examples and formal definitions, the reader deserves a quick

explanation for this somewhat bizarre statement. A propositional proof
system in a general sense is simply a non-deterministic algorithm accepting
exactly the set of propositional tautologies in De Morgan language. The
main problem is the NP vs. coNP problem. This is a question whether some
propositional proof system admits polynomial size proofs of all tautologies
(i.e. whether some proof system can run in polynomial time). For a few
particular proof systems based on logic or algebraic calculi (e.g. resolution or
Nullstellensatz) super-polynomial lower bounds are known. All these lower
bounds can be proved for a very uniformly given sequences of tautologies:
For \( n \geq 1 \), the \( n \)-th tautology asserts the validity of a combinatorial principle
on structures of size \( n \) (e.g. the pigeonhole principle). The principle can be
formulated as a statement that a sentence in a first-order language (or in
a simple 2nd order extension allowing for natural formulation of Ramsey
theorem and alike) has no model (of size \( n \)). The sentence then makes sense
over arbitrary structures in the language, even infinite. The general theory
of limits of proof systems we are after says that given a proof system \( P \), if
instances of a principle \( \Phi \) for \( n \geq 1 \) are valid and proved by \( P \) in length
polynomial in \( n \) then \( \Phi \) holds true (in the definable sense - see Definition
1.1) in a class of first-order structures associated with \( P \). Such a class of
structures is informally called a covering class of \( P \). If a covering class is an
elementary class, i.e. the class of models of a theory, we shall call the theory
a covering theory.

In fact, any \( P \) admits a covering class and one can take for the class a
class of suitable generic expansions of models of bounded arithmetic. How-
ever, we look for model-theoretically natural classes as this then yields an
insight into lower bounds for \( P \). There are two prominent examples known
at present. The tree-like resolution proof system \( R^* \) (in fact, its extension
\( R^* (\log) \)) corresponds to the class of all infinite structures ([12, 15]). Here
"corresponds to" means that the covering relation actually characterizes all
first order principles with polynomial size \( R^*(\log) \)-proofs. The second exam-
ple is Nullstellensatz and polynomial calculus over a finite prime field \( \mathbb{F}_p \). Its
covering class is the class of Euler structures with a suitable Grothendieck
ring ([14]).

In this paper we first define the notion of the combinatorics of a first
order structure \( M \) and give few examples. Then we recall the translation
of first-order principles into propositional formulas; we consider a particular
translation that produces a set of clauses (or a set of polynomial equations).

In the third section we define the covering relation between first order
structures and propositional proof systems, formalizing a relation that ex-
ists between all structures and (an extension) of tree-like resolution, and
between Euler structures and Nullstellensatz and polynomial calculus over
a finite prime field. Structure \( M \) covers a propositional proof system \( P \)
iff \( M \) combinatorially satisfies all \( \Phi \) for which the associated sequence of
propositional formulas \( \langle \Phi \rangle_n \), encoding that \( \Phi \) holds in \( L \)-structures of size
\( n \), have polynomial size \( P \)-proofs. Finding \( M \) that covers \( P \) but does not
combinatorially satisfy \( \Phi \) thus gives a super polynomial lower bound for the
size of \( P \)-proofs of \( \langle \Phi \rangle_n \).

We use the covering theories for (an extension of) tree-like resolution
[12, 15], and for Nullstellensatz and polynomial calculus systems over a finite
prime field [14] to give new lower bounds for these systems, for principles that
are not apparently amenable to other known methods. This is in Section 4.

In Section 5 we give a general description of a covering class of any \( P \) as
expansions of models of bounded arithmetic.

Finally, in the last section, we show that (classes of) structures with r.e.
combinatorics can be seen as propositional proof systems in a natural way.

Definitions of undefined notions in model theory and proof complexity
can be found in [7] and [12] respectively. Logarithms are base 2 and \([n] := \{0, \ldots, n - 1\}\).

1 Combinatorics of a structure

Let \( L \) be any first order relational language with constants and with equality.
The prohibition of general function symbols is not essential but it simplifies
some definitions. A suitable general language is the language of directed
graphs: a binary relation symbol and constants; any theory is interpretable
in a theory in this language (see e.g. [9]\(^1\)).

Let \( M \) be a first order structure with at least two different elements. To
avoid any confusion we shall assume that \( L \) is disjoint from the language of
\( M \). The qualification definable means definable with parameters, unless it
is specified otherwise. An \( L \)-structure is definable in \( M \) if, for some \( k > 1 \),
it\( s \) universe is a definable subset of \( M^k \) and all \( L \)-relations are definable in
\( M \).

Let \( \Phi \) be an \( L \)-sentence.

\(^1\)This is the only reference I know of where this is explicitly stated and proved. However,
undoubtedly other authors had to use a similar statement earlier.
Definition 1.1 $M$ combinatorially satisfies $\Phi$, $M \models_c \Phi$ in symbols, iff $\Phi$ holds in all $L$-structures definable in $M$. The combinatorics of $M$ is the set

$$\text{Comb}(M) := \{ \Phi \mid M \models_c \Phi \}$$

It would be, perhaps, equally natural to consider $L$-structures interpretable in $M$ (e.g. in the sense of being definable in $M^o$) rather than only definable. But for our purposes the given definition suffices.

As all finite structures are definable in all $M$ of size at least 2, Comb($M$) is a subset of sentences valid in finite structures (hence the name combinatorics of $M$). It is clearly deductively closed. Moreover, it can be non-trivial, i.e. bigger than just predicate logic but smaller than the set of all sentences valid in finite structures.

Example 1.2 Let $\mathbb{R}$ be the real closed field in the language of ordered fields. Comb($\mathbb{R}$) violates the pigeonhole principle (PHP) but still upholds that there is no bijection between a set and the set minus one point (the ontoPHP), and that there is no injective map of $A^2$ into $A$ (the weak pigeonhole principle, WPHP), if $|A| > 1$.

The PHP is violated by many maps in $\mathbb{R}$; for example, map $x > 0$ to $x + 1$ and leave $x \leq 0$ in place. The ontoPHP holds as semi-algebraic bijections preserve Euler characteristic and the characteristics of a set and the set minus one point differ, cf. [5]. The WPHP holds for dimension reasons.

Example 1.3 Let $\mathbb{C}$ be the complex field in the language of rings. Comb($\mathbb{C}$) contains Comb($\mathbb{R}$), as $\mathbb{C}$ is definable in $\mathbb{R}$, but it is different. Namely, C fulfills PHP; this is a theorem of Ax [1]. However, the dual statement:

Any $f : A \to A$ that is onto must be one-to-one

is clearly not in Comb($\mathbb{C}$) (e.g. $x \to x^2$).

Ax’s theorem states that for any algebraic set $A$ any one-to-one polynomial map $p : A \to A$ must be onto. For a proof of the Ax’s theorem utilizing compactness see e.g. [18, p.2, Thm.1.3]. The proof works equally well in a bigger generality and gives the following statement: Any $\forall \exists$ $L$-sentence

\footnote{The difference is that the universe of a definable structure is a definable set and the equality is absolute, while in an interpretable structure the universe can be a quotient of a definable set modulo a definable relation, or a quotient of a quotient, etc., and the equality is not absolute.}
\(\Phi\) that is valid in all finite \(L\)-structures is also combinatorially valid in all structures that are elementarily equivalent to ultraproducts of locally finite structures (in the case of \(\mathbb{C}\) it is the ultraproduct of algebraic closures of finite fields).

**Example 1.4** If \(M\) is pseudo-finite (i.e., elementarily equivalent to an ultraproduct of finite structures) then \(\text{Comb}(M)\) consists exactly of \(\Phi\)’s valid in all finite structures.

As the theory of \(M\) gets stronger, \(\text{Comb}(M)\) gets weaker.

**Example 1.5** If \(M\) is a model of Peano arithmetic \(PA\) (or even its subtheory \(I\Sigma_1^0\)) that is \(\Sigma_1^0\)-sound (\(M\) satisfies the same universal sentences that are true in the standard model \(\mathbb{N}\)) then \(\text{Comb}(M)\) consists exactly of \(\Phi\) provable in predicate logic.

This follows straightforwardly from the completeness theorem which can be formalized in \(I\Sigma_1^0\), cf. [6].

We mention two problems whose motivation will be clear later.

**Problem 1.6** Characterize structures \(M\) whose combinatorics \(\text{Comb}(M)\) contains the following principle of finite combinatorics: Every partial ordering has a minimal element.

The qualification *characterize* means that we look for a property of such structures of a natural model-theoretic character. For example, structures combinatorially satisfying PHP are those admitting ordered weak Euler characteristic on definable sets, cf. [17].

**Problem 1.7** When is \(\text{Comb}(M)\) recursively enumerable? Are there some mathematically interesting structures with non-trivial but recursively enumerable combinatorics? Are \(\text{Comb}(\mathbb{C})\) and \(\text{Comb}(\mathbb{R})\) r.e.?

2 First order principles and propositional formulas

A sentence \(\Phi\) gives raise to an infinite sequence of propositional formulas.
**Definition 2.1** The propositional language \( \langle L \rangle \) consists of connectives 1 (true), 0 (false), \( \neg \), of \( \lor \) and \( \land \) of unbounded arity, and of infinitely many atoms 

\[
p^R_{i_1, \ldots, i_k}
\]

one for every relation symbol \( R(x_1, \ldots, x_k) \in L \) and every choice of natural numbers \( i_1, \ldots, i_k \)

The next definition recalls a standard notation [12].

**Definition 2.2** Let \( \Phi \) be an \( L \)-sentence and \( n \geq 1 \) a natural number. Define the propositional formula \( \langle \Phi \rangle_n \) in language \( \langle L \rangle \) by induction on the logical complexity of \( \Phi \):

1. \( \langle i = j \rangle_n \) is 1 iff \( i = j \), otherwise it is 0, for any \( i, j < n \).
2. \( \langle R(i_1, \ldots, i_k) \rangle_n := p^R_{i_1, \ldots, i_k} \), for any \( i_1, \ldots, i_k < n \)
3. \( \langle \neg \Phi \rangle_n := \neg \langle \Phi \rangle_n \)
4. \( \langle \Phi \circ \Psi \rangle_n := \langle \Phi \rangle_n \circ \langle \Psi \rangle_n \), for \( \circ = \lor, \land \)
5. \( \langle \exists \, x, \Phi(x) \rangle_n := \lor_{i < n} \langle \Phi(i) \rangle_n \)
6. \( \langle \forall \, x, \Phi(x) \rangle_n := \land_{i < n} \langle \Phi(i) \rangle_n \)

The formula \( \langle \Phi \rangle_n \) is, in general, a constant depth formula while some proof systems operate with only restricted class of formulas (like resolution with clauses) or even with formulas that are not DeMorgan (like algebraic proof systems), or even do not operate with formulas at all (like a general NP algorithms). Strictly speaking, this does not need to concern us as, by definition, a proof system proves all tautologies in DeMorgan language. For example, a general formula is encoded for resolution by limited extension.

However, the tautologies we consider are of special form and there is a better way of reaching propositional formulas of the CNF form. The sentence \( \Phi \) is valid in all finite structures iff its Herbrandization \( \Phi_H \) is; \( \Phi_H \) is an \( \exists \forall \) formula and \( \neg \Phi_H \) is a CNF formula.

The Herbrandization of a prenex formula \( \Phi \):

\[
\exists x_1 \forall y_1 \ldots \exists x_k \forall y_k; \phi(x, y)\]

\( \phi \) open formula in DNF form, is

\[
\exists x_1 \ldots \exists x_k; \phi(x, y_1/h_1(x_1), y_2/h_2(x_1, x_2), \ldots, y_k/h_k(x))
\]
where $h_i$ are new function symbols. As we do not allow function symbols, each $h_i$ is replaced by $(i + 1)$-ary relation symbol $H_i(x_1, \ldots, x_i, z)$, and $\Phi_H$ is defined to be the disjunction of the formula

$$\exists x_1 \ldots \exists x_k \exists y_1 \ldots \exists y_k; H_1(x_1, y_1) \land H_2(x_1, x_2, y_2) \land \ldots$$

$$\land H_k(x_1, y_k) \land \phi(x_1, \ldots, y_k)$$

together with the formula

$$\exists x_1 \forall y_1 \neg H_1(x_1, y_1) \lor \ldots \lor \exists x_1, \ldots, x_k \forall y_k \neg H_k(x_1, \ldots, x_k, y_k)$$

Hence $\langle \Phi_H \rangle_n$ is a DNF formula and so, possibly always replacing $\Phi$ by $\Phi_H$, we may assume henceforth without loss of generality that all $\Phi$ translate to a sequence of DNF formulas $\langle \Phi \rangle_n$.

An analogous translation is used in [19, 20].

3 Covering theories for proof systems

Let $M$ be a structure and $P$ a proof system.

**Definition 3.1** The symbol $P \vdash_\ast \langle \Phi \rangle_n$ denotes the existence of $P$-proofs of $\langle \Phi \rangle_n$ of size $n^{O(1)}$, for all $n \geq 1$.

$M$ covers $P$ if $\Phi \in \text{Comb}(M)$ whenever $P \vdash_\ast \langle \Phi \rangle_n$.

Our main goal in this research is to find, given $P$, a rich class of structures $M$ defined by some combinatorial, model-theoretic or geometric property, and covering $P$. We use the informal term covering class of $P$ for any such class. The point is that one can then use structures in the covering class for proving lower bounds for $P$: to prove super-polynomial lower bound for $\langle \Phi \rangle_n$ it is sufficient to find $M$ in the class such that $M \not\models c\Phi$.

---

\footnote{The referee pointed out that it is not a priori clear that two logically equivalent sentences give two sequences of tautologies of polynomially related proof complexity. This will be indeed true for any $P$ containing $R^m(\log)$ as (the Herbrand translation of) one sentence has polynomial size $R^m(\log)$-proofs from the other one (i.e. one does not operate with the Herbrand translation of the equivalence but with proofs of one sentence from the other one).}
3.1 First example: an extension of tree-like resolution

Resolution \( R \) is naturally a subsystem of sequent calculus \( LK \), allowing no connectives except the negation. The following definition augments \( R \) as to correspond to \( LK \)-proofs of the \( \Sigma \)-depth 0 (as defined in [10] or [12, Def. 12.2.3]).

**Definition 3.2 ([15])** (a) \( R^+ \) is a refutation proof system that works with clauses \( C \) formed by conjunctions \( D_i \) of literals \( \ell_{i,j} \):

\[
C = \bigcup_i \{D_i\}, \quad D_i = \bigwedge_j \ell_{i,j}
\]

The inference rules are:

\[
\frac{C_1 \cup \{\Lambda_j \ell_j\} \quad C_2 \cup \{-\ell'_1, \ldots, -\ell'_k\}}{C_1 \cup C_2}
\]

provided \( \ell'_1, \ldots, \ell'_k \) are among \( \ell_j \)'s and \( k \geq 1 \), and

\[
\frac{C_1 \cup \{\Lambda_{i<j} \ell_j\} \quad C_2 \cup \{\Lambda_{j<i} \ell_{i+j}\}}{C_1 \cup C_2 \cup \{\Lambda_{j<i} \ell_j\}}
\]

(b) Let \( f : \mathbb{N} \rightarrow \mathbb{N} \) be a function. The \( R(f) \)-size of an \( R^+ \)-proof is the minimum \( S \) such that the proof has at most \( S \) clauses and each conjunction of literals occurring in clauses has size at most \( f(S) \).

We shall use a phrase \( R(f) \)-proofs of size \( S \) rather than \( R^+ \)-proofs of \( R(f) \)-size \( S \).

(c) Tree-like versions of proof systems are denoted by the superscript \(^* \): \( R^*, R(f)^* \).

Obviously, \( R(1) \) is just \( R \), while \( R(\log) \) is the \( \Sigma \)-depth 0 subsystem of \( LK \).

**Theorem 3.3 ([12, L.9.5.2])** Any structure covers \( R^*(\log) \).

The theorem is valid in a stronger sense than is captured by the notion of covering. Namely, a principle has polynomial size \( R^*(O(1)) \) proofs iff it is provable in predicate logic and, if it is not, then it requires exponential size \( R^*(\log) \) proofs. This first example of a covering class is from [12], where the lower bound part of the theorem is a special case of a more
general statement about search trees. The upper bound (principles provable in predicate logic have polynomial size $R^*(O(1))$-proofs) follows from the simulation of bounded arithmetic by $R^+$ constructed already in [10]. See [15] for further discussion. We state now explicitly this stronger version of Theorem 3.3 as it will be used in Theorem 4.1. For the sake of the completeness of the presentation we also outline the construction from [12].

**Theorem 3.4 ([12, L.9.5.2],[10])** Let $\Phi$ be a first order sentence. Then there are $\epsilon > 0$ and $k \geq 1$ such that the following holds:

1. If $\neg \Phi$ has an infinite model then $\langle \Phi_H \rangle_n$ requires $R^*(\log)$-proof of size at least $2^{n^{1/2}}$, for all $n \geq 1$.

2. If $\Phi$ is valid in all infinite structures then $\langle \Phi_H \rangle_n$ admits $R^*(k)$-proofs of size polynomial in $n$, for all $n \geq 1$ for which $\langle \Phi \rangle_n$ is a tautology.

**Proof-sketch:**

Let $\Phi$ be an $L$-sentence and $L_H$ the relational language of $\Phi_H$. If $\Phi$ can be violated in an infinite structure, so can be $\Phi_H$. Let $M$ be an infinite $L_H$-structure in which $\neg \Phi_H$ holds. Let $k \geq 1$ be the maximal arity of a relation symbol in $L_H$ (hence $k$ depends on $L$ and on the number of quantifiers in $\Phi$ only). Let $n \geq 1$.

Assume that $\pi$ is an $R^*(\log)$ refutation of $\langle \Phi_H \rangle_n$ of size $s = 2^t$, i.e. the sizes of the conjunctions in clauses are bounded by $t$.

A partial bijection $F$ between a subset $\text{dom}(F) \subseteq [n]$ and a subset $\text{rng}(F) \subseteq M$ determines a partial truth assignment $\alpha_F$ to atoms of $\langle \Phi_H \rangle_n$: If $p_{i_1,\ldots,i_m}$ is an atom and $\{i_1,\ldots,i_m\} \subseteq \text{dom}(F)$ then $\alpha_F$ gives the atom the truth value of $R(F(i_1),\ldots,F(i_m))$ in $M$.

Construct a sequence of clauses $C_i$ from $\pi$ and partial bijections $F_i$ between subsets of $[n]$ and of $M$ by the following process. Put $C_0 := \emptyset$, $F_0 := \emptyset$ and $\pi_0 := \pi$. Pick a clause $C_1$ in $\pi$ splitting the proof tree in a 1/3-2/3 fashion of Spira’s lemma. Consider two cases: (a) there is $F \supseteq F_0$ such that $\alpha_F$ forces $C_1$ true, and (b) there is no such $F$. In case (a) take for $F_1$ some $F \supseteq F_0$ with the property and of minimal size. In case (b) take $F_1 := F_0$. Clearly $|F_1| \leq tk$.

In case (a) we delete from $\pi$ everything above $C_1$, in case (b) everything that is not above $C_1$. The resulting tree $\pi_1$ is a proof of (a) either the empty clause from the original initial clauses and from a clause forced true by $F_1$, (b) or it is a proof from original initial clauses of a clause that can never be forced true by any $F \supseteq F_1$. 

9
Next we analogously pick $C_2$ splitting $\pi_1$ in the 1/3-2/3 fashion and define $F_2$ and $\pi_2$ identically, and continue in this process until we reach, in step $w$, $\pi_w$ of size 1. Any $\pi_i$ in the process is a proof from original initial clauses or from clauses forced true by $F_i$ of a clause that can never be forced true by any $F \supseteq F_i$. Note that $w \leq \log^{3/2} s \leq O(t)$.

Now we reach a contradiction: $C_w$ must be an original initial clause that cannot be forced true by $F \supseteq F_w$. However, as $M$ satisfies $\neg \Phi_H$, as long as there is a room to extend $F_w$ such $F$ exists. That is, we get a contradiction if $n - |\text{dom}(F_w)| \geq tk$. Hence $t \geq \Omega((n/k)^{1/2})$ and so $s \geq 2^{\epsilon n^{1/2}}$ for $\epsilon = \Omega(k^{-1/2})$. This explains part (1).

In part (2) the hypothesis implies that $\Phi_H$ is provable in predicate calculus. The simulation of first order proofs (of bounded arithmetic even) in [10] produces a tree-like $R^+$-proof of polynomial size (there is no $\#$-function so we do not get a quasi-polynomial bound). The sizes of the conjunctions in the clauses are bounded by the size of the open kernel of $\Phi_H$, i.e. by some constant $k \geq 1$ independent of $n$ (in the case of bounded arithmetic the bound gets polylogarithmic because we work with sharply bounded kernels instead).

q.e.d.

Riis [20] has recently proved a sharper version of Theorem 3.4 for $R^*$. Namely, under the same assumptions: In (1) \langle$\Phi$\rangle require $R^*$-proofs of size $2^{\Omega(n)}$ rather than $2^{\Omega(n^{1/2})}$, and in (2) \langle$\Phi$\rangle have polynomial size $R^*$-proofs (so $k = 1$). Riis [20] stresses the dichotomy form of his theorem under the name "complexity gap".

The idea to use pure model theory for lower bounds in proof complexity (via the relation formalized here as covering) is from [14] where our second example is proved.

3.2 Second example: algebraic proof systems

An algebraic proof system seeks to prove that $f_0 \in \langle f_1, \ldots, f_k \rangle$, given polynomials $f_i \in F[\overline{F}]$ over a field $F$. A proof of the ideal membership in the so called \textit{Nullstellensatz proof system} NS (cf. [2]), is a $k$-tuple $g_1, \ldots, g_k$ of polynomials from $F[\overline{F}]$ such that $\sum_{i \geq 1} g_i \cdot f_i = f_0$. The degree of the NS proof is $\max_{i \geq 1} \deg(g_i f_i)$.

A proof of the ideal membership in \textit{polynomial calculus} PC is a sequence of polynomials $h_1, \ldots, h_4$ such that $h_4 = f_0$, and such that every $h_j$ is either
one of \( f_1, \ldots, f_k \), or is derived from earlier \( h_1, \ldots, h_{j-1} \) by one of the two rules: \( g_1, g_2 \) entail any \( F \)-linear combination of \( g_1, g_2 \), and \( g \) entails any \( x_i \cdot g \). The degree of the PC proof is \( \max_i \deg(h_i) \). We shall denote the systems \( \text{NS} / F \) and \( \text{PC} / F \) respectively when we want to stress the particular underlying field \( F \).

Polynomials are encoded using the dense notation, i.e., by listing all coefficients, even zero, of all monomials up to the degree of the polynomial. For \( F \) finite the size of the code of \( f \) is thus proportional to \( n^{\deg(f)} \), \( n \) the number of variables. Hence polynomial size \( \text{NS} \)- or \( \text{PC} \)-proofs over finite fields are exactly proofs of bounded degree.

Given propositional formula \( \psi \) with binary \( \lor \) and \( \land \) define polynomial \( \psi^* \) by: for atom \( p \), \( p^* := p \). Further, \( (\psi \lor \phi)^* := \psi^* \cdot \phi^* \) and \( (\neg \psi)^* := 1 - \psi^* \) (the truth values TRUE and FALSE are represented by 0 and 1 respectively). Note that \( \deg(\psi^*) \) depends on the logical depth of \( \psi \) only.

Now take a first order sentence \( \Phi \), and we assume that it is in the Herbrand form. Assign to \( \Phi \) the following set of polynomials:

- \( \sum_{j \in [n]} p^{H_t}_{i_1, \ldots, i_t, j} = 1 \), one for each \( t = 1, \ldots, k \), and \( i_1, \ldots, i_t, j \in [n] \)
- \( p^{H_t}_{i_1, \ldots, i_t, j_1} \cdot p^{H_t}_{i_1, \ldots, i_t, j_2} = 0 \), one for each \( t = 1, \ldots, k \), and \( i_1, \ldots, i_t, j_1, j_2 \in [n] \)
- \( [H_1(i_1, j_1) \land \cdots \land H_k(i_1, \ldots, i_k, j) \land \neg \phi(t, j)]^* = 0 \), one for each choice of \( \tilde{i}'s \) and \( \tilde{j}'s \) in \([n] \)
- \( p^{2} - p = 0 \), any atom \( p \).

Solutions to the polynomial system are in one-to-one correspondence with satisfying assignments of \( \neg \langle \Phi \rangle_n \). Hence \( \langle \Phi \rangle_n \) is a tautology iff the polynomial system has no solution iff the polynomials generate the trivial ideal (the last set of polynomials allows to look only on solutions in \( F \) rather than in \( F^\text{alg} \), the algebraic closure of \( F \), in order to apply Nullstellensatz). Hence, whenever we work with algebraic systems we shall work with the polynomial system as the propositional translation of \( \Phi \), and we shall denote the systems also \( \langle \Phi \rangle_n \).

**Theorem 3.5 ([13, Thm.5.5])** For \( \text{NS} \) and \( \text{PC} \) over a finite prime field \( \mathbb{F}_p \) and any \( \Phi \) it holds:

\[
\text{NS} / \mathbb{F}_p \vdash_s \langle \Phi \rangle_n \iff \text{PC} / \mathbb{F}_p \vdash_s \langle \Phi \rangle_n
\]

That is, a structure covers \( \text{NS} / \mathbb{F}_p \) iff it covers \( \text{PC} / \mathbb{F}_p \).
Definition 3.6 ([14, Def.2.1]) Let $M$ be a first-order structure. $\text{Def}^k(M)$ is the class of subsets of $M^k$ definable in $M$ (with parameters) and $\text{Def}^\infty(M)$ is the union $\bigcup_k \text{Def}^k(M)$.

Let $R$ be a commutative ring with unity. A function

$$\chi : \text{Def}^\infty(M) \to R$$

is an abstract Euler characteristic on $M$ over $R$ iff it satisfies the following conditions:

1. $\chi(\{a\}) = 1$, any $a \in M^k$.

2. $\chi(A \cup B) = \chi(A) + \chi(B)$, whenever $A, B, A \cup B \in \text{Def}^\infty(M)$ and $A, B$ are disjoint.

3. $\chi(A \times B) = \chi(A) \cdot \chi(B)$, whenever $A, B, A \times B \in \text{Def}^\infty(M)$.

4. $\chi(A) = \chi(B)$, whenever $A, B \in \text{Def}^\infty(M)$ and there is a definable bijection between $A$ and $B$.

5. $\chi(A) = c \cdot \chi(B)$, whenever $c \in R, A, B \in \text{Def}^\infty(M)$ and there is a definable map $f$ with domain $A$ and range $B$ such that each its fiber $f^{-1}(b), b \in B$, has Euler characteristic $\chi(f^{-1}(b)) = c$.

A pair $(M, \chi/R)$ satisfying this conditions is called Euler structure.

**Theorem 3.7 ([14, Thm.6.1])** Let $\mathbb{F}_p$ be a finite prime field.

Then any structure $M$ admitting Euler characteristic over all $\mathbb{Z}/(p^n)$, $\nu \geq 1$, covers $\text{NS}/\mathbb{F}_p$, and hence also $\text{PC}/\mathbb{F}_p$.

4 Examples of new lower bounds

In this section we give examples of applications of the covering theories and we derive lower bounds for principles of a type that does not seem to be easily amenable to other known methods.

Let $T$ be the theory of fields in the usual language of rings except that $+$ and $\cdot$ are represented by relations, and let $T_q$ be $T$ together with the axiom that the characteristic is some specific $q > 0$. Consider the following statements obviously valid for finite fields:

$\Phi_1$ A field of characteristic $q$ is perfect:

$$\bigwedge T_q \to \forall y \exists x, x^q = y$$
$\Phi_2$ A field is commutative:

$$\bigwedge T \rightarrow \forall x, y; x \cdot y = y \cdot x$$

$\Phi_3$ A field is not algebraically closed (a special case):

$$\bigwedge T \rightarrow \exists y_1, y_2 \forall x; x^2 + y_1 x + y_2 \neq 0$$

$\Phi_4$ A field cannot be ordered:

$$\bigwedge T \rightarrow \neg A$$

where $A$ is a sentence in the language of $T$ augmented by $<$ and expressing that $<$ is a linear ordering respecting the field operations.

$\Phi_5$ Two fields of different characteristic cannot share a common universe:

$$\bigwedge T_q' \rightarrow \neg \bigwedge T_q''$$

where $q'$, $q''$ are two different primes and $T'$, $T''$ two copies of theory $T$ in disjoint languages.

**Theorem 4.1** All principles $\Phi_1, \ldots, \Phi_5$ require proofs of size $\exp(n^{O(1)})$ in $R^*(\log)$.

**Proof:**
We apply Theorem 3.4. It is enough to find infinite models (fields) in which the respective principles fail.

$\Phi_1$: There is an infinite imperfect field of characteristic $q$.

$\Phi_2$: Quaternions.

$\Phi_3$: $C$.

$\Phi_4$: $R$.

$\Phi_5$: Two countable fields of different characteristic can sit on $\mathbb{N}$.

q.e.d.

**Theorem 4.2** Let $p > 0$ be prime. Then principles $\Phi_i$, $i = 2, 3, 4$, require proofs of superpolynomial size (i.e., of non-constant degree) in both $NS/\mathbb{F}_p$ and $PC/\mathbb{F}_p$.
Proof:
We apply Theorem 3.7. The real field $\mathbb{R}$ admits Euler characteristic in $\mathbb{Z}$ (see [14] or [5]) and hence also in all $\mathbb{Z}/(p^n)$. Quaternions and complex numbers are interpretable in $\mathbb{R}$ and so admit such Euler characteristic too. Thus examples in cases $\Phi_i$, $i = 2, 3, 4$, from the proof of Theorem 4.1 work here equally well (via Theorem 3.7).

q.e.d.

To prove a similar lower bound for $\Phi_1$ it would be enough to construct an imperfect field of characteristic $q$ that admits Euler characteristic in all $\mathbb{Z}/(p^n)$, $n \geq 1$. To prove a lower bound for $\Phi_5$ one would need to amalgamate two countable fields (in disjoint languages) of different characteristic admitting the Euler characteristic into one structure admitting it too. A starting point can be a theorem Hrushovski [8] that it is possible to amalgamate two algebraically closed fields of different characteristics (strongly minimal structures, in particular) into one strongly minimal structure.

5 A generic construction

In this section we describe a class of structures covering a given proof system $P$. It is a class of certain expansion of models of bounded arithmetic and its definition explicitly refers to $P$. Thus it is not a good covering class in the sense that it does not bring new insight about the system. However, it was one of the original motivations for covering theories to understand combinatorics behind constructions of the expansions via model theoretic forcing and it offers some intuition how to search for a useful covering class for any $P$.

Let $M$ be an arbitrary countable model of true arithmetic in the usual language, and let $n \in M$ be any non-standard element. Denote by $M_n$ the structure with the universe $\{ u \in M \mid u < n \}$ in language $L_n$; $L_n$ is the language with a relation symbol $R_X$ for every subset $X \subseteq (M_n)^k$, all $k \geq 1$, that is definable in $M$. Note that $M_n$ satisfies induction for all $L_n$-formulas.

Let $P$ be a proof system. Proofs, formulas and evaluations are encoded by relations on $M_n$. Let $Prf_P(a, \alpha, \sigma, \gamma)$ be a first order $L_n$-formula such that for some $\ell \in \mathbb{N}$ the $\Sigma_1^1$ formula $\exists U \subseteq m^\ell; Prf_P(m, \alpha, \sigma, U)$ defines the relation "$\alpha$ is a $P$-proof of size $\leq m$ of $\sigma$".

Similarly let $Sat(a, \beta, \sigma, \delta)$ be a first order formula such that for some $\ell$ the $\Pi_1^1$ formula $\forall V \subseteq m^\ell; Sat(m, \beta, \sigma, V)$ defines the relation "$\beta \subseteq m$ is
a truth evaluation satisfying formula $\sigma \subseteq m$. Here we use the fact that the property inside "..." is polynomial-time and hence also, in particular, expressible by a $\Pi^1_1$-formula. Such formulas exist by Fagin’s theorem (or by a direct construction, cf. [11, 12]).

Consider formula $R f n_P$ with set variables $\alpha, \beta, \gamma, \delta, \sigma$:

$$\forall x; [Prf_P(x, \alpha, \sigma, \gamma) \land \gamma \subseteq x] \rightarrow (\delta \subseteq x' \rightarrow Sat(x, \beta, \alpha, \delta))$$

Note that $R f n_P$ is valid in $M_n$.

Let $L'$ be any language extending $L_n$. Define a class $C_P$ consisting of $L'$-structures that are expansions of $M_n$ and that satisfy $R f n_P$ for all instances obtained by substituting for $\alpha, \beta, \gamma, \delta, \sigma$ definable relations. The class $C_P$ is non-empty; for example, it contains all expansions of $M_n$ in which the new $L'$-relations are definable already in $M_n$. Such structure satisfies $R f n_P$ because $M_n$ does.

We assume that $P$ is strong enough in the next theorem. If a particular proof system does not satisfy the hypothesis we can replace it by a stronger proof system that does; a covering class of the stronger system is also a covering class of the original weaker one.

**Theorem 5.1** Let $P$ be a proof system that contains a Frege system $F$, and let $C_P$ be the associated class of structures. Then any structure from $C_P$ covers $P$.

**Proof:**

Assume that some $N \in C_P$ does not cover $P$. That means that there is $\Phi$ such that

(i) all $\langle \Phi \rangle_k, k \in \mathbb{N}$, have polynomial size $P$-proofs

(ii) but $\Phi \notin \text{Comb}(N)$.

We use the assumption $P \supseteq F$ to strengthen (i). Let $D$ be a new unary predicate symbol not in $L'$, and let $\Phi^D$ be the relativization of $\Phi$ to $D$. Then we have

(i') all $\langle \Phi^D \rangle_k, k \in \mathbb{N}$, have polynomial size $P$-proofs.

This is because there are, given $k$, polynomial size (DeMorgan) formulas $\beta_{ij}$ $(i, j < k)$ with atoms for statements $u \in D$ ($u < k$) such that Frege system $F$ proves in polynomial size that $\beta_{ij}$ define a graph of a bijection between
\( D \) and some initial segment \( \{0, 1, \ldots, w - 1\} \) of \( k \). This is because \( F \) can count (see [3] or [12]).

Property (ii) means that there is an \( L \)-structure \( K \subseteq M'_n \) definable in \( N \) that violates \( \Phi \). Structure \( K \) defines an evaluation for atoms of \( \langle \Phi^D \rangle_k \), \( k = n' \), that does not satisfy the formula; in particular, predicate \( D \) is interpreted by the universe of \( K \). On the other hand, as \( M \) is a model of true arithmetic, there is \( \pi \in L_n \) that is a \( P \) proof of \( \langle \Phi \rangle_k \). This gives an instance of \( Rfn_P \) that is not true, violating the definition of the class \( C_P \).

q.e.d.

**Problem 5.2** For which proof systems \( P \) does it hold that if \( P \vdash_n (\Phi)_n \) then also \( P \vdash_n (\Phi^D)_n \)? In particular, does this hold for resolution?

Any structure combinatorially satisfying \( \Phi \) also combinatorially satisfies \( \Phi^D \). Hence if the problem is answered negatively for a proof system \( P \), no covering class for \( P \) can characterize principles with polynomial \( P \)-proofs exactly.\(^4\)

The simplest case in Theorem 5.1 is when \( L' \) extends \( L_n \) by \( L \), and \( N \in C_P \) expands \( M_n \) by an \( L \)-structure on \( M_n \) with a suitable property. Such expansions can be constructed, in principle, by forcing (see [11], [12]).

We remark that for many proof systems the axiom scheme \( Rfn_P \) is actually equivalent to an induction scheme for formulas of particular form (depending on the system) or, equivalently, to a principle that any linear ordering definable by formulas of a particular type has the least element (this motivates Problem 1.6). See [15] for description of this for resolution and its extension, and [12] for a more general information.

One would like to further replace \( Rfn_P \) or the equivalent induction axiom by a transparent combinatorial principle, as it is done for \( R^*(\log) \) and \( NS/Fp, PC/Fp \) by their covering theories. However, for these proof systems the combinatorial characterization of polynomial provability is valid only for proofs of \( (\Phi)_n \) and not for proofs of arbitrary sequences of tautologies. One might not be able to replace \( Rfn_P \) by a transparent combinatorial principle without the restriction to uniform sequences \( (\Phi)_n \). No such general characterization is known for any proof system at present. On the other hand, the restriction to \( (\Phi)_n \) may allow such combinatorial description of polynomial provability for stronger systems. Particularly interesting would be the cases of resolution \( R \) and cutting planes proof system \( CP \).

\(^4\)I owe this remark to the referee.
6 Structures as proof systems

If $\text{Comb}(M)$ is r.e., then it defines a proof system. Little bit more generally we define

**Definition 6.1** Let $\mathcal{C}$ be a class of structures. Put $\text{Comb}(\mathcal{C}) := \bigcap_{M \in \mathcal{C}} \text{Comb}(M)$. Assume that $\text{Comb}(\mathcal{C})$ is recursively enumerable, and let $\mathcal{M}$ be a Turing machine that enumerates the set.

Define a proof system $A_\mathcal{C}$ as follows: a string $\pi$ is a proof of formula $\sigma$ in the system iff

- $\pi$ is a quadruple $\langle \Phi, n, w_1, w_2 \rangle$ where $\Phi \in \text{Comb}(\mathcal{C})$, $w_1$ is a computation of $\mathcal{M}$ certifying this membership, and $w_2$ is an $R^*(\log)$-proof of $\sigma$ from $\langle \Phi \rangle_n$.

We shall denote the proof system $A_M$ when $\mathcal{C}$ consists of just a single structure $M$.

Recall that a proof system $P$ polynomially simulates a proof system $Q$ iff there is a polynomial time algorithm translating any $Q$-proof $\pi$ of $\sigma$ into a $P$-proof $\pi'$ of the same formula, and that $P$ simulates $Q$ iff such $\pi'$ exists polynomially bounded in the length of $\pi$ (but is not necessarily construable by a polynomial time algorithm).

**Lemma 6.2** Let $\mathcal{C}$ be a class of infinite structures such that $\text{Comb}(\mathcal{C})$ is recursively enumerable. Then

1. $A_\mathcal{C}$ polynomially simulates $R^*(\log)$.
2. If $\Psi \in \text{Comb}(\mathcal{C})$ then $A_\mathcal{C} \vdash_r \langle \Psi \rangle_n$.
3. $\mathcal{C}$ covers $A_\mathcal{C}$.
4. Assume $P \vdash_r \langle Rf_{nP} \rangle_n$, all $n \in \mathbb{N}$. If all structures in $\mathcal{C}$ cover a proof system $P$ then $A_\mathcal{C}$ simulates $P$.

**Proof**:

Parts 1. and 2. of the lemma are direct consequences of the definition $A_\mathcal{C}$.

Part 3. follows from Theorem 3.4. Assume $\Psi \notin \text{Comb}(\mathcal{C})$, and that $\Psi$ is already in the Herbrand form. Hence there is an infinite structure
\[ M \in \mathcal{C} \text{ in which } \Psi \text{ combinatorially fails. For the sake of contradiction assume that } A_C \vdash_s \langle \Psi \rangle_n, \text{ say } \langle \Psi \rangle_n \text{'s are provable in size } n^k, k \geq 1 \text{ a suitable constant. This means that } \langle \Psi \rangle_n \text{ is provable in } R^*(\log) \text{ from some } \langle \Phi \rangle_m \text{ for some } \Phi \in \text{Comb}(\mathcal{C}) \text{ (also in Herbrand form); necessarily } m \leq n^k. \text{ More precisely, all clauses of } \neg \langle \Phi \rangle_m \text{ are provable in size } \leq n^k \text{ from the clauses of } \neg \langle \Psi \rangle_n. \]

Now \( \Phi \) holds in \( M \). So we can take the assumed proof of any one clause of \( \neg \langle \Phi \rangle_m \) and apply the same construction as in the proof of Theorem 3.4, using \( M \) as the reference structure. The only difference is that we do not pick \( F_0 := \emptyset \) but any minimal \( F_0 \) such that no \( F \supseteq F_0 \) makes the clause of \( \neg \langle \Phi \rangle_m \) true. Such \( F_0 \) exists by the fact that \( \Phi \) holds in \( M \). The contradiction is reached as before, using that \( \Psi \) fails in \( M \).

We shall use bounded arithmetic for Part 3. By the hypothesis of Part 3 the proof system \( P \) polynomially proves formulas \( \langle Rfn_P \rangle_n \). Hence \( Rfn_P \in \text{Comb}(\mathcal{C}) \). Further, \( R^*(\log) \) augmented by instances of \( \langle Rfn_P \rangle_n \) simulates \( P \); this follows from the fact that \( R^*(\log) \) simulates the theory \( S^2_2(\alpha) \) ([10], [15]) and this theory proves that \( Rfn_P \) implies that all \( \sigma \)'s with a \( P \)-proof are tautologies. In particular, \( S^2_2(\alpha) \) proves the implication
\[
(\delta \subseteq x^k \land \text{Sat}(x, \beta, \sigma', \delta)) \rightarrow \sigma
\]
where \( \beta \) is the assignment consisting of \( \overline{p} \), atoms of \( \sigma \), and \( \sigma' \) in the antecedent is the set coding the formula \( \sigma \).

q.e.d.

Note that the hypothesis of part 3. is satisfied by many proof systems, e.g., by \( R(\log) \) or \( F \) (cf. [16, 12]). In fact, with a more sophisticated formulation of \( Rfn_P \) one can show that \( R^*(\log) \) also satisfies the hypothesis.

The first example restates Example 1.5.

**Example 6.3** \( M \) is a sound model of \( I\Sigma^0_1 \) then \( A_M \) is defined (i.e., \( \text{Comb}(M) \) is recursively enumerable) and \( A_M = R^*(\log) \).

Recall that \( M \) is pseudo-finite iff it is elementarily equivalent to an ultraproduct of finite structures.

**Example 6.4** If \( M \) is pseudo-finite then \( \text{Comb}(M) \) is a complete \( \Pi^0_1 \) set and hence \( A_M \) is not defined.
This is because Comb(M) is then exactly the set of sentences true in finite structures and Trachtenbrot’s theorem applies.

**Example 6.5** Weak Euler characteristic is a function satisfying properties 1.-4. of Definition 3.6. The class of structures admitting weak Euler characteristic has recursively enumerable combinatorics.

The combinatorics of the class is axiomatized by instances of the ontoPHP principle, as by [14] this principle characterizes weak Euler structures.

Note that examples from Problem 1.7 would also give examples of these new ”structure based” proof systems.

**Acknowledgement:** I am indebted to the anonymous referee for valuable comments and suggestions, and to S. Buss (San diego) for suggesting few language corrections.
